## ABSTRACT

**Context.** Stellar streams are a consequence of the tidal forces produced by a host galaxy on its satellites. Since the self-gravity of cold stellar streams can be considered negligible, they constitute excellent probes of the gravitational potential of the host galaxy. For this reason, some Milky Way (MW) stellar streams have been used to put constraints on the dark matter (DM) mass and shape, allowing to test different DM halo distributions. Traditional studies typically involve phenomenological  $\Lambda$ CDM halos or *ad hoc* DM profiles with different degree of triaxiality, which preclude to gain insights into the nature and mass of the DM particles. Recently, a Maximum Entropy Principle of halo formation has been applied to provide a DM halo model which incorporates the fermionic (quantum) nature of the particles, while leading to DM profiles which depend on the fermion mass. Such profiles develop a more general *dense core - diluted halo* morphology able to explain the galaxy rotation curves, while the degenerate fermion core can mimic the central massive black holes (BHs).

**Aims.** We attempt to model the GD-1 stellar stream using a spherical *core-halo* DM distribution for the host, which, at the same time, explains the dynamics of the S-cluster stars through its degenerate fermion-core with no central BH.

**Methods.** We used two optimization algorithms in order to fit both the initial conditions of the stream orbit and the fermionic model. We modelled the baryonic potential with a bulge and two disks (thin and thick) with fixed parameters according to the recent literature. The stream observables are 6D phase-space data from the Gaia DR2 survey.

**Results.** We were able to find good fits for both the GD-1 stream and the S-stars for a family of fermionic *core-halo* profiles parameterized by the fermion mass. Particle masses are constrained in the range  $56 \text{ keV}/c^2$  -with corresponding DM core of  $\sim 10^3$  Schwarzschild radius- all the way to  $360 \text{ keV}/c^2$  corresponding to the most compact core of 5 Schwarzschild radius prior to the gravitational collapse into a BH of about  $4 \times 10^6 M_\odot$ . The DM configurations have a virial radius of 27 kpc and a virial mass of  $1.4 \times 10^{11} M_\odot$ , the latter being at  $2\sigma$  from a previous Milky Way DM halo mass estimate using the Sagittarius stream. The circular velocity at the position of the Sun,  $v_c(R_\odot)$ , is not assumed in the model but an outcome; we obtained  $v_c(R_\odot) \approx 244 \text{ km s}^{-1}$  in agreement with recent independent estimates. We have computed the acceleration field along the stream and compared with the corresponding quantity produced by another potential model that also fits the GD-1 stream, obtaining perfect agreement.

**Conclusions.** This work provides further evidence that stellar streams constitute trustworthy systems for the measurement of the acceleration field of the Galaxy, and that the *core-halo* fermionic model is a reliable model for both the massive central object and the DM of the Galaxy. Remarkably, this model predicts a total MW mass of  $2.3 \times 10^{11} M_\odot$  which is in agreement with recent mass estimates obtained from Gaia DR3 rotation curves (Gaia RC). In summary, with one single fermionic model for the DM distribution of the MW, we obtain a good fit in three totally different distance scales of the Galaxy:  $\sim 10^{-6}$  kpc (central, S-stars),  $\sim 14$  kpc (mid, GD-1) and  $\sim 30$  kpc (boundary, Gaia RC mass estimate).

**Key words.** Galaxy: kinematics and dynamics – Galaxy: halo – dark matter

## 1. Introduction

The gravitational interaction between a galaxy and a satellite (a dwarf galaxy or a globular cluster) modifies both systems: the host galaxy strips stars from the satellite at a rate that depends on their density profiles and on the orbit, while the density profile of the host suffers a reorganization of its matter in the vicinity of the satellite's orbit, developing a wake due to the dynamical friction. The ensemble of stars tidally stripped from the satellite constitute a so-called stellar stream (also known as tidal stream);

examples of them have been detected in the Milky Way (MW), Andromeda and the Local Volume (?).

At present, stellar streams constitute one of the main MW observables related to the dynamics, together with other baryonic observables like the Galaxy rotation curve, the radial surface density profile of the disk, and the vertical density profile of the disk at the solar radius. Tidal streams probe the acceleration field produced by the Galaxy (Johnston et al. 1999; Zhao et al. 1999; Law et al. 2009; Lux et al. 2013; Johnston & Carlberg 2016; Ibata et al. 2016; Ibata et al. 2017; Thomas et al. 2017; Reino et al. 2021) as well as its formation history according to Helmi et al. (1999), Helmi (2020), Ramos et al. (2022), and Cunning-

\* e-mail: mmestre@fcaglp.unlp.edu.ar

ham et al. (2023), among others. Indeed, a stellar stream could be the closest realization of a galactic orbit that can be observed in Nature. Nevertheless, the larger the progenitor, the more the discrepancy between its orbit and the stream phase-space configuration. In fact, the taxonomy of streams is very rich (Amorisco 2015) because of the different gravitational configurations that can take place, going from almost one-dimensional streams whose progenitor is a small globular cluster, to wide shells produced by the partially radial sinking of a large progenitor into the MW centre. Besides, it is theoretically possible to have an accreted stream whose progenitor is a globular cluster orbiting a MW's satellite galaxy, giving rise to stellar cocoons around the stream track (Carlberg 2018; Malhan et al. 2019, 2021; Gialluca et al. 2021; Qian et al. 2022).

Stream data together with other measurements from baryonic tracers can help in making claims about an unknown aspect of the gravitational field: whether to model it with a dark matter (DM) halo component, or a Modified Newtonian Dynamics (MOND) theory is needed. For example, within the DM paradigm, spatial densities might have different profiles (e.g. spherical, axisymmetric, triaxial) depending on the number of conserved components of the angular momentum, which also influences the stream properties (Vera-Ciro & Helmi 2013; Price-Whelan et al. 2016; Mestre et al. 2020). In particular, Malhan & Ibata (2019) have constrained the MW dark matter halo shape using Gaia DR2 data of the GD-1 stream, assuming an axisymmetric generalization of the NFW profile and obtaining a flattening halo parameter of  $q = 0.82^{+0.25}_{-0.13}$ , thus compatible with spherical symmetry. Moreover, Palau & Miralda-Escudé (2023) were able to measure the oblateness in an axisymmetric generalization of the NFW profile using three stellar streams: NGC 3201, M68 and Palomar 5, obtaining consistency with a spherical halo.

In addition to the above traditional halo models, which arise from  $\Lambda$ CDM cosmologies or from various ad hoc symmetry considerations, there are DM profiles that take into account the quantum nature of the DM candidate: see e.g. Schive et al. (2014) for bosonic profiles (composed of axion-like particles), and Ruffini et al. (2015); Chavanis et al. (2015); Argüelles et al. (2021) for fermionic profiles (typically composed of sterile neutrinos). A relevant aspect of such kind of profiles is the source of quantum pressure acting in the innermost regions of the halos: while in the boson case the profiles develop a highly dense soliton, in the fermion case the profiles develop a degenerate compact core surrounded by a more dilute halo which is self-bounded in radius. In this work we focus on the latter. Such a *dense core – diluted halo* fermionic DM profile is obtained from the fully relativistic Ruffini-Argüelles-Rueda (RAR) model, which was successfully applied to different galaxy types (Argüelles et al. 2019; Krut et al. 2023) including the Milky Way from Sagittarius A\* till the entire halo (Argüelles et al. 2018; Becerra-Vergara et al. 2020, 2021; Argüelles et al. 2022). This kind of model built in terms of a Fermi-Dirac-like phase space distribution function (including for central degeneracy and cut-off in the particle energy), is also named as the relativistic fermionic King model (Chavanis 2022b).

In this paper we model the 6D track of the GD-1 stellar stream inside a MW with a fermionic dark matter core-halo distribution. At the same time, we aim to explain the dynamics of the S-cluster stars through the high density fermion-core and without assuming a central BH. Finally we compare the virial mass of the Galaxy as predicted by the fermionic model with that obtained from recent Gaia DR3 rotation curve data. In Sec. 2 we explain the methodology; in Sec. 3 we present the best-fit results, and in Sec. 4 we give the conclusions.

## 2. Methodology

In this section we explain the observables and methods used in this research. The exact pipeline applied in order to obtain the results and plots of this paper can be found at the following GitHub repository<sup>1</sup>: [https://github.com/martinmestre/stream-fit/blob/main/pipeline\\_paper/](https://github.com/martinmestre/stream-fit/blob/main/pipeline_paper/).

### 2.1. Observables and assumed measurements

The main observables that we have used were computed with the polynomial fits found by Ibata et al. (2020) for the GD-1 stream using astrometric (Gaia DR2), photometric and high-precision spectroscopic datasets, together with the analysis of the STREAMFINDER algorithm. The polynomials are the following:

$$\phi_2 = 0.008367\phi_1^3 - 0.05332\phi_1^2 - 0.07739\phi_1 - 0.02007, \quad (1)$$

$$D = -4.302\phi_1^5 - 11.54\phi_1^4 - 7.161\phi_1^3 + 5.985\phi_1^2 + 8.595\phi_1 + 10.36, \quad (2)$$

$$\tilde{\mu}_\alpha = 3.794\phi_1^3 + 9.467\phi_1^2 + 1.615\phi_1 - 7.844, \quad (3)$$

$$\mu_\delta = -1.225\phi_1^3 + 8.313\phi_1^2 + 18.68\phi_1 - 3.95, \quad (4)$$

$$v_h = 90.68\phi_1^3 + 204.5\phi_1^2 - 254.2\phi_1 - 261.5, \quad (5)$$

with  $\phi_1$  and  $\phi_2$  in radians,  $D$  in kpc,  $\tilde{\mu}_\alpha = \mu_\alpha \cos \delta$  and  $\mu_\delta$  in  $\text{mas yr}^{-1}$  and  $v_h$  in  $\text{km s}^{-1}$ . These quantities correspond to the longitude and latitude in the GD-1 celestial frame of reference (Koposov et al. 2010); the heliocentric distance; the proper motion in right ascension and declination, and the heliocentric radial velocity respectively. The domain of the polynomials is limited to  $-90^\circ < \phi_1 < 10^\circ$ . To obtain our observable data set we sampled the domain with 100 equidistant points ( $\phi_1^{(i)}$ ,  $i = 1, \dots, 100$ ) and evaluated the polynomials at those points, thus obtaining the sets  $\phi_1^{(i)}$ ,  $\phi_2^{(i)}$ ,  $D^{(i)}$ ,  $\tilde{\mu}_\alpha^{(i)}$ ,  $\mu_\delta^{(i)}$  and  $v_h^{(i)}$ . In one of the experiments we will consider an ‘observable’ of a different nature, the core mass ( $M_{\text{core}}$ ), which is defined as the mass enclosed at the radius when the circular velocity reaches its first maximum. The constraint for the mass of the core of the distribution is assumed to be  $M_{\text{core}} = 3.5 \times 10^6 M_\odot$  in agreement with Becerra-Vergara et al. (2020, 2021); Argüelles et al. (2022). The core radius does not include all the mass inside the innermost S-star pericenter here considered (S2), because the first maximum of the circular velocity corresponds to a shorter distance in which the core density-region is still falling. Indeed, in Sec. 3 we obtain a DM mass inside the S2 star pericenter of  $M(r_{\text{peri-S2}}) = 4.03 \times 10^6 M_\odot$ , in excellent agreement with the Schwarzschild BH mass constraints of  $4.1 \times 10^6 M_\odot$  and  $3.97 \times 10^6 M_\odot$  obtained from the same S2 star in GRAVITY Collaboration et al. (2018) and Do et al. (2019) respectively. The parameters assumed in this paper are the Galactocentric distance of the Sun  $R_\odot = 8.122 \text{ kpc}$  (GRAVITY Collaboration et al. 2018) and the Sun’s peculiar velocity<sup>2</sup>  $\mathbf{v}_{\odot p} = (11.1 \text{ km s}^{-1}, 12.24 \text{ km s}^{-1}, 7.25 \text{ km s}^{-1})$  (Schönrich et al. 2010).

<sup>1</sup> After acceptance of the paper, the pipeline repository will become public and this footnote removed.

<sup>2</sup> We adopted a Cartesian reference frame ( $X, Y, Z$ ) with corresponding velocities ( $U, V, W$ ) in which the  $X$  and  $U$  axes point from the Galactic center towards the opposite direction of the Sun;  $Y$  and  $V$  point in the direction of the Galactic rotation at the location of the Sun; and  $Z$  and  $W$  point towards the North Galactic Pole. Note that this is the same right-handed reference system adopted by Astropy.

## 2.2. The fermionic DM halo model

Our fermionic DM model is a spherical and isotropic distribution of fermions at finite temperature in hydrostatic equilibrium subject to the laws of General Relativity (GR), i.e. the T.O.V equations complemented with the Tolman, Klein and particle energy conservation along the geodesic as defined in Argüelles et al. (2018) and detailed below. For numerical purposes, in this work we use a somewhat different dimensionless nomenclature for the variables with respect to Argüelles et al. (2018). Thus the metric together with the mass and hydrostatic equilibrium (i.e. T.O.V) equations read, respectively:

$$ds^2 = g_{00}(r)dt^2 + g_{11}(r)dr^2 - r^2 d\theta^2 - r^2 \sin\theta d\phi^2, \quad (6)$$

$$\frac{dz}{d\zeta} = -1 + e^{2\zeta-z} \frac{\rho(r)}{\rho_{\text{rel}}}, \quad (7)$$

$$\frac{dv}{d\zeta} = \frac{1}{2} \left[ e^z + e^{2\zeta} \frac{P(r)}{\rho_{\text{rel}} c^2} \right] [1 - e^z]^{-1}, \quad (8)$$

where

$$g_{00}(r) = e^{\nu(r)}, \quad (9)$$

$$g_{11}(r) = -e^{\lambda(r)}, \quad (10)$$

$$\zeta = \ln(r/R), \quad (11)$$

$$z = \ln\psi, \quad (12)$$

$$\psi = 1 - e^{-\lambda(r)} = \frac{M_{\text{DM}}(r) R}{M}, \quad (13)$$

$$\rho(r) = \frac{4\rho_{\text{rel}}}{\sqrt{\pi}} \int_1^\infty \epsilon^2 [\epsilon^2 - 1]^{1/2} f(r, \epsilon) d\epsilon, \quad (14)$$

$$P(r) = \frac{4\rho_{\text{rel}} c^2}{3\sqrt{\pi}} \int_1^\infty [\epsilon^2 - 1]^{3/2} f(r, \epsilon) d\epsilon, \quad (15)$$

$$R^2 = \frac{c^2}{8\pi G \rho_{\text{rel}}}, \quad (16)$$

$$M = 4\pi R^3 \rho_{\text{rel}}, \quad (17)$$

$$\rho_{\text{rel}} = \frac{g\pi^{3/2} m^4 c^3}{h^3}, \quad (18)$$

where  $G$  is the gravitational constant,  $c$  is the speed of light,  $h$  is the Planck constant,  $m$  is the fermion mass,  $M_{\text{DM}}(r)$  is the DM mass enclosed up to radius  $r$ ,  $\rho(r)$  is the density,  $P(r)$  is the pressure and  $\nu(r)$  is the metric exponent. By combining the definitions of  $R$  and  $M$ , it leads to the familiar relation  $R = 2GM/c^2$ .

The phase-space function  $f$  is given by a Fermi-Dirac distribution with energy cutoff, and is well motivated as can be obtained from a maximum entropy principle applied on kinetic theories including the physics of self-gravity and violent relaxation as shown in Chavanis 2004 (for a review see also Chavanis 2022a), and recently applied to a vast sample of disk galaxies in Krut et al. (2023):

$$f(r, \epsilon) = \begin{cases} \frac{1 - e^{[\epsilon - \epsilon_c(r)]/\beta(r)}}{1 + e^{[\epsilon - \alpha(r)]/\beta(r)}} & \text{if } \epsilon \leq \epsilon_c(r), \\ 0 & \text{otherwise,} \end{cases} \quad (19)$$

with  $\alpha(r)$  the chemical potential (including rest mass),  $\epsilon_c(r)$  the cutoff energy (including rest mass) and  $\beta(r)$  the effective temperature.

The above equations should be complemented with two thermodynamic equilibrium conditions given in Tolman (1930)

and Klein (1949) together with the condition of energy conservation along the geodesic given in Merafina & Ruffini (1989):

$$\frac{1}{\alpha} \frac{d\alpha}{dr} = \frac{1}{\beta} \frac{d\beta}{dr} = \frac{1}{\epsilon_c} \frac{d\epsilon_c}{dr} = -\frac{1}{2} \frac{dv}{dr}. \quad (20)$$

It is not possible to integrate these equations from  $r = 0$  because  $\zeta(r)$  diverges at the origin. Therefore, the following approximations for the initial conditions at a value  $r_{\text{min}} \gtrsim 0$  were used:

$$\nu(r_{\text{min}}) = \frac{1}{6} \frac{\rho_0}{\rho_{\text{rel}}} \left[ \frac{r_{\text{min}}}{R} \right]^2 \equiv \tau, \quad (21)$$

$$\psi(r_{\text{min}}) = \frac{1}{3} \frac{\rho_0}{\rho_{\text{rel}}} \left[ \frac{r_{\text{min}}}{R} \right]^2 = 2\tau, \quad (22)$$

which implies

$$\frac{r_{\text{min}}}{R} = \sqrt{6\tau \frac{\rho_{\text{rel}}}{\rho_0}}, \quad (23)$$

where  $\rho_0 \equiv \rho(0)$  and  $\tau \equiv 10^{-15}$ . Since the right hand side of Eq. (6) does not depend on the metric (only on its derivative), we can add a constant  $\nu_0$  to the solution in order to satisfy a condition of continuity with the Schwarzschild metric at the border of the fermion distribution, obtaining:

$$\nu_0 = 2 \ln \left( \frac{\beta_b}{\beta_0} \sqrt{1 - \psi_b} \right), \quad (24)$$

where  $\psi_b$  and  $\beta_b$  are quantities evaluated at the border, that is when  $\rho(r_b) \rightarrow 0^3$ .

The system of equations thus obtained has four free parameters:  $m$ ,  $\alpha_0 = \alpha(0)$ ,  $\beta_0 = \beta(0)$ , and  $\epsilon_{c0} = \epsilon_c(0)$ , but in practice we will use the following related quantities:  $m$ ,  $\beta_0$ ,  $\theta_0 = (\alpha_0 - 1)/\beta_0$ , and  $W_0 = (\epsilon_{c0} - 1)/\beta_0$ . Sometimes we will use  $\omega_0 = W_0 - \theta_0$  instead of  $W_0$ .

Equations (6)-(20) were solved using a PYTHON (Van Rossum & Drake Jr 1995) script<sup>4</sup> that makes use of the NumPy (Virtanen et al. 2020) and SciPy (Harris et al. 2020) libraries, under the LSODA algorithm as solver. We used relative and absolute tolerance parameters given by  $\text{rtol} = 5 \times 10^{-14}$  and  $\text{atol} = 0$ , respectively.

## 2.3. Milky Way and stream models

We modelled our Galaxy by combining the fermionic dark halo described above — whose parameters will be determined in this work — with a fixed baryonic component identical to the one in Model I of Poulidas et al. (2017). We name this full Galaxy model as Fermionic-MW.

Besides the above mentioned model, and for comparative purposes, we will make use of the Galactic model fitted by Malhan & Ibata (2019), which is the MWPotential2014 model plus an axisymmetric NFW profile. This fitted model uses a circular velocity at the position of the Sun  $v_c(R_\odot) = 244 \pm 4 \text{ km s}^{-1}$  and a  $z$ -flattening of the DM density distribution  $q_p = 0.82^{+0.25}_{-0.13}$ . We name this Galaxy model as NFW-MW.

<sup>3</sup> Numerically the border was defined as the radius in which the density decays to  $\rho_b = 10^{-10} M_\odot \text{ pc}^{-3}$ .

<sup>4</sup> model\_def.py

Since GD-1 is a dynamically cold stream, with its stars keeping a large degree of correlation, its almost one-dimensional distribution in phase-space could be well approximated with the orbit of a theoretical progenitor (unobserved). Other fact that supports the modelling of the stream as an orbit is that there has not been any observation of the characteristic "S"-feature (Malhan & Ibata 2019; de Boer et al. 2018; Malhan et al. 2018; Price-Whelan & Bonaca 2018).

The initial conditions of the orbit were given in the spherical equatorial coordinates of the ICRS frame: right ascension  $\alpha$ , declination  $\delta$ ,  $D$ ,  $\tilde{\mu}_\alpha$ ,  $\mu_\delta$ , and  $v_h$ . The code uses the *Astropy* ecosystem (Astropy Collaboration et al. 2022, 2018, 2013) in order to transform these initial conditions to Galactocentric coordinates assuming a Galactocentric reference frame with the Sun at the position  $\mathbf{x}_\odot = (-R_\odot, 0, 0)$  and a Sun's velocity given by the sum of the circular velocity at the position of the Sun and the Sun's peculiar velocity:  $\mathbf{v}_\odot = \mathbf{v}_{\odot p} + (0, v_c(R_\odot), 0)$ . The circular velocity depends on the model and position and is given by

$$\begin{aligned} v_c^2(R_\odot) &= R_\odot |\nabla \Phi(\mathbf{x})|_{\mathbf{x}=\mathbf{x}_\odot} \\ &= R_\odot |\nabla \Phi_B(\mathbf{x})|_{\mathbf{x}=\mathbf{x}_\odot} + G \frac{M_{\text{DM}}(R_\odot)}{R_\odot} \end{aligned} \quad (25)$$

where  $\Phi$  is the total potential and  $\Phi_B$  is the potential generated by the three baryonic components. In the last term, we have used the spherical symmetry of the DM distribution in order to relate the acceleration with the enclosed mass.

We integrated the orbit forwards and backwards in time during a time interval of  $\Delta t = 0.2$  Gyr, starting in both cases from a given initial condition for the progenitor. In the next sections we will explain how these initial conditions were chosen for some simulations, and fitted for others. The integrator used is a Runge-Kutta of order eight (DOP853 called from *SciPy*'s `solve_ivp` function) with relative and absolute tolerance parameters given by `rtol` =  $5 \times 10^{-14}$  and `atol` =  $0.5 \times 10^{-14}$ , respectively.

The resulting orbit was successively transformed to the ICRS and then to the GD-1 frames of coordinates. For the latter we used the `GD1Koposov10` class defined in the *Gala* package (Price-Whelan 2017; Price-Whelan et al. 2020) which uses the transformation matrix defined by Koposov et al. (2010). After these transformations we obtained the orbit expressed in the observable variables  $\phi_1$ ,  $\phi_2$ ,  $D$ ,  $\tilde{\mu}_\alpha$ ,  $\mu_\delta$ ,  $v_h$ . Finally, we computed these variables at the points  $\phi_1^{(i)}$  by interpolation. These values, together with the observed GD-1 data defined in Sec. 2.1, were used to evaluate the following stream function:

$$\chi_{\text{stream}}^2 = \chi_{\phi_2}^2 + \chi_D^2 + \chi_{\tilde{\mu}_\alpha}^2 + \chi_{\mu_\delta}^2 + \chi_{v_h}^2 \quad (26)$$

$$\chi_\eta^2 = \frac{1}{\sigma_\eta^2} \sum_{i=1}^{100} (\eta^{(i)} - \eta(\phi_1^{(i)}))^2 \quad (27)$$

where  $\eta \in \{\phi_2, D, v_h, \tilde{\mu}_\alpha, \mu_\delta\}$ , and  $\sigma_\eta$  are the corresponding dispersions of the stream data points estimated by inspection of Figs. 1, 3, and 4 of Ibata et al. (2020):  $\sigma_{\phi_2} = 0.5^\circ$ ,  $\sigma_D = 1.5$  kpc,  $\sigma_{v_h} = 10$  km s $^{-1}$ , and  $\sigma_{\tilde{\mu}_\alpha} = \sigma_{\mu_\delta} = 2$  mas yr $^{-1}$ . Thus,  $\chi_{\text{stream}}^2$  measures the departure of the model from the observed stream.

For some fits we will also consider the departure of the model from a dark mass constraint in the core of the distribution:

$$\chi_{\text{core}}^2 = \frac{(m_c - M_{\text{core}})^2}{\sigma_m^2}, \quad (28)$$

where the value of  $M_{\text{core}}$  was defined in Sec. 2.1,  $m_c$  is the core mass of the model (i.e. variable), and  $\sigma_m$  was fixed at  $0.01 M_{\text{core}}$ .

For these fits we will then use the following compound function:

$$\chi_{\text{full}}^2 = \chi_{\text{stream}}^2 + \chi_{\text{core}}^2. \quad (29)$$

We note that in order to compute the estimated core mass for each model,  $m_c$  in Eq. (28), we need to calculate the first local maximum of the circular velocity in GR, the latter compactly expressed as:

$$V_{\text{circ,DM}}(r) = c \left( \frac{r g'_{00}(r)}{2 g_{00}(r)} \right)^{1/2} = c \left( \frac{r}{2} \frac{dv(r)}{dr} \right)^{1/2}, \quad (30)$$

where the velocity has components  $V^i = dx^i/dt$  ( $i = 1, 2, 3$ ) measured in a local frame that is fixed in space at a distance  $r$  from the Galaxy centre. From the T.O.V Eq. (8) it is possible to show that this relativistic formula for the velocity tends to the classical law i.e.  $\sqrt{G M(r)/r}$ , when being far from the core.

#### 2.4. Optimization algorithms

Our goal is to fit our Fermionic-MW model by minimizing the full  $\chi^2$  function given by Eq. (29) (when fitting the NFW-MW model we will use only the function given by Eqs. (26) and (27)). To this end we will use two optimization algorithms. One is *SciPy*'s `optimize.differential_evolution` algorithm, with metaparameters given by `strategy="best2bin"`, `maxiter`=200, `popsiz`=200, `tol`= $5 \times 10^{-8}$  and `atol`=0, unless otherwise stated. This method can be run in parallel with shared memory.

The other algorithm is an implementation of the Mesh Adaptive Direct Search algorithm called *NOMAD* (Audet et al. 2021). The *JULIA* (Bezanson et al. 2017) wrapper of this algorithm, *NOMAD.jl*, was used through the package *Optimization.jl*. We used default values of all the metaparameters except for `maxiters`=700.

### 3. Results

#### 3.1. Fitting the Fermionic-MW model

We fitted both the Fermionic-MW model parameters and the initial conditions (IC) of the orbit of the progenitor through four steps that consisted in: (i) obtaining an order zero value of the orbit IC using the NFW-MW model, (ii) fitting the Fermionic-MW parameters with fixed IC values, (iii) polishing the IC values with fixed Fermionic-MW potential and (iv) polishing the Fermionic-MW parameters with fixed IC values.

As a first step we searched for a provisional but good enough set of IC that can reproduce the orbit in our Fermionic-MW model. To this end, we fitted the initial conditions in the fixed NFW-MW model by using the  $\chi_{\text{stream}}^2$  function as defined in Eq. (26) and the differential evolution algorithm specified in Sec. 2.4. Since the optimization algorithm needs bounds for the variables, we used boxes centered near the midpoint of the observable data, i.e.  $\eta^{(51)}$ , that corresponds to  $\alpha = 149^\circ 24'$ ,  $\delta = 36^\circ 61'$ ,  $D = 7.69$  kpc,  $\tilde{\mu}_\alpha = -5.70$  mas yr $^{-1}$ ,  $\mu_\delta = -12.48$  mas yr $^{-1}$  and  $v_h = -18.81$  km s $^{-1}$ , and with sides of length equal to the absolute values of the variables at their centers (except for  $\alpha$ , where we have used a side of length  $\alpha/5$ ).

The differential evolution algorithm converged to the solution  $\alpha = 149^\circ 28'$ ,  $\delta = 36^\circ 62'$ ,  $D = 7.95$  kpc,  $\tilde{\mu}_\alpha = -5.59$  mas yr $^{-1}$ ,  $\mu_\delta = -12.48$  mas yr $^{-1}$  and  $v_h = -19.33$  km s $^{-1}$ , with a value of  $\chi_{\text{stream}}^2 = 17.52$ . The orbit that corresponds to these IC is displayed in the observable space in Fig. 1 (top:  $\phi_2$ , middle:  $\tilde{\mu}_\alpha$ ,

**Fig. 1.** Stream fits in astrometric observable space: sky position (top:  $\phi_2$ ) and proper motions (middle:  $\tilde{\mu}_\alpha$ , bottom:  $\mu_\delta$ ).

bottom:  $\mu_\delta$ ) and Fig. 2 (top:  $D$ , bottom:  $v_h$ ) with a dotted (green) line. The solid (black) line shows the corresponding observable data  $\eta$ , while the shaded (grey) area demarcates the corresponding  $1\sigma_\eta$  regions.

Previous works (Argüelles et al. 2018; Argüelles et al. 2019; Krut et al. 2023) have shown that the parameters of the fermionic DM model can be split into two sets for the family of fermionic DM profiles with highly degenerate cores (i.e.  $\theta_0 \gtrsim 15$  Argüelles et al. 2019). On one hand,  $m$  and  $\beta_0$  control the core of the distribution in the sense that, for given values of  $M_{\text{core}}$  and  $m$ , it is possible to find a consistent value of  $\beta_0$  with a very small influence of the other two parameters  $\theta_0$  and  $W_0$ . This implies a partial degeneracy between  $m$  and  $\beta_0$ . On the other hand, for the same kind of fermionic *core-halo* solutions with positive central degeneracy mentioned above, the main behaviour of the distribution in the halo is determined by  $\omega_0$  as explicated in Argüelles et al. (2019) for different galaxy types.

As a starting point for the fitting of the Fermionic-MW parameters (second step), we took the values obtained by Becerra-Vergara et al. (2020):  $(m, \beta_0, \theta_0, W_0) = (56 \text{ keV c}^{-2}, 1.1977 \times 10^{-5}, 37.765, 66.3407)$ , which allow their MW model (DM+barions) to satisfy the geodesic motions of both S2 and G2 at Sagittarius A\* and the rotation curve from Sofue (2013). From these values, fixing  $m = 56 \text{ keV c}^{-2}$  and taking the already fitted IC of the stream progenitor for the NFW-MW model, we performed a differential evolution min-

**Fig. 2.** Stream fits in observable space: photometric distance (top:  $D$ ) and spectroscopic heliocentric velocity (bottom:  $v_h$ ).

imization of the  $\chi^2_{\text{full}}$  function in the window  $(\theta_0, \omega_0, \beta_0) \in [35, 40] \times [25, 30] \times [10^{-5}, 1.5 \times 10^{-5}]$ . Using metaparameter values `maxiter` = `popsize` = 300, the algorithm converged to  $(\theta_0, \omega_0, \beta_0) = (36.069, 27.349, 1.253 \times 10^{-5})$ , giving  $\chi^2_{\text{stream}} = 21.9632$  and  $\chi^2_{\text{core}} = 1.5142 \times 10^{-8}$ .

The third step consists in polishing the IC of the orbit by using the differential evolution algorithm with fixed Fermionic-MW parameters, with metaparameter values `maxiter` = `popsize` = 400, which gave a result very similar to that of the FMW-MW case:  $\alpha = 149^\circ 59'$ ,  $\delta = 37^\circ 09'$ ,  $D = 7.96 \text{ kpc}$ ,  $\tilde{\mu}_\alpha = -5.61 \text{ mas yr}^{-1}$ ,  $\mu_\delta = -12.40 \text{ mas yr}^{-1}$  and  $v_h = -22.60 \text{ km s}^{-1}$ , with an improved value of  $\chi^2_{\text{stream}} = 19.32$ .

The last step consisted in polishing the fermionic parameters using the second optimization algorithm described in Sec. 2.4, i.e. NOMAD. We divided a macroscopic orthohedron in parameter space,  $(\theta_0, \omega_0, \beta_0) \in [35.8, 36.3] \times [27.0, 27.6] \times [1.2 \times 10^{-5}, 1.3 \times 10^{-5}]$ , in 16 smaller orthohedrons. In each subregion we performed an independent optimization, in a parallel distributed scheme, searching for those parameters that minimize  $\chi^2_{\text{full}}$ . Then, we selected the global minimum by comparing the results of each distributed process obtaining the following final fitted parameters of the model:  $(\theta_0, \omega_0, \beta_0) = (36.033, 27.3225, 1.2539 \times 10^{-5})$ , giving  $\chi^2_{\text{full}} = 19.18$ . The corresponding orbit is displayed in the observable space in Figs. 1–2 with a dashed (amber) line. It can be seen that both the Fermionic-MW and NFW-MW models fit the GD-1 stream very well. We have not performed any statistically rigorous comparison between both models to determine which one is more consistent with the data.

It is instructive to see how the value of  $\chi^2_{\text{stream}}$  is modified when the parameters  $\theta_0$  and  $\omega_0$  (i.e., those that control the halo) are varied. To this end, we fixed  $(m, \beta_0) = (56 \text{ keV c}^{-2}, 1.254 \times 10^{-5})$ , and varied  $(\theta_0, \omega_0)$  in a grid spanning the rectangle  $[34, 38] \times [25, 30]$ . Fig. 3 shows a contour plot of this grid coloured by the value of their corresponding  $\chi^2_{\text{stream}}$ ; the black point corresponds to our fitted solution. It can be noticed that the minima of the function are located along a thin valley, so the solution of the fitting problem is locally degenerate-like along a

**Fig. 3.** Values of  $\chi^2_{\text{stream}}$  for  $(m, \beta_0) = (56 \text{ keV } c^{-2}, 1.254 \times 10^{-5})$  in the window  $(\theta_0, \omega_0) \in [34, 38] \times [25.5, 28.2]$ . The black point corresponds to our solution and the grey region corresponds to  $\chi^2_{\text{stream}} > 10^4$ . It can be seen that the minima of the function are located along a thin valley.

**Fig. 4.** Values of  $\chi^2_{\text{stream}}$  for  $(m, \beta_0) = (56 \text{ keV } c^{-2}, 1.254 \times 10^{-5})$  in the window  $(\theta_0, \omega_0 - h(\theta_0)) \in [35, 37] \times [-0.011, 0.011]$ . The grey region corresponds to  $\chi^2_{\text{stream}} > 500$ .

straight line in the  $(\theta_0, \omega_0)$  plane. To see the behaviour of  $\chi^2_{\text{stream}}$  around the solution, we first fitted a line to those points that satisfy  $\chi^2_{\text{stream}} < 50$ , obtaining  $h(x) = 0.7967 + 0.7362x$ ; then subtracted this line to  $\omega_0$ , and finally remade a plot of  $\chi^2_{\text{stream}}$  in the window  $(\theta_0, \omega_0 - h(\theta_0)) \in [35, 37] \times [-0.011, 0.011]$ . The result can be seen in Fig. 4. It is noticeable that indeed there exists a minimum (non-degenerate problem) and that the variance along  $\omega_0 - h(\theta_0)$  is two orders of magnitude smaller than the variance along  $\theta_0$ .

### 3.2. Rotation curves, accelerations and virial quantities

We computed the resulting rotation curves for our two models and compared them with three observed rotation curves (Fig. 5).

The dotted (green) line corresponds to the NFW-MW model and the dashed (amber) one to the Fermionic-MW model. The observed rotation curves are coded according to: triangles (purple) for Eilers et al. (2019), rhombi (light-blue) for Sofue (2020)

**Fig. 5.** Rotation curves of the Fermionic-MW model (this work, in dashed amber) and NFW-MW model (Malhan & Ibata (2019), in dotted green) which fit the GD-1 stream, are compared *a posteriori* with different observed rotation curves (Eilers et al. 2019 with purple triangles, Sofue 2020 with light-blue rhombi, and Jiao et al. 2023 with black circles). Only the Fermionic MW model can account for both, the GD-1 stream data and the sharp drop of the recent GAIA DR3 rotation curve.

and circles (black) for Jiao et al. (2023). It is worth noticing that Sofue (2020) assumes  $(R_\odot, v_c(R_\odot)) = (8 \text{ kpc}, 238 \text{ km s}^{-1})$ , while Eilers et al. (2019) assumes  $R_\odot = 8.122 \text{ kpc}$  and a Galactocentric Sun's velocity  $v_\odot = (11.1, 245.8, 7.8) \text{ km s}^{-1}$ , with which they estimated  $v_c(R_\odot) = 229 \pm 0.2 \text{ km s}^{-1}$ .

It is interesting to note that both theoretical models, Fermionic-MW and NFW-MW, give  $v_c(R_\odot) \approx 244 \text{ km s}^{-1}$  at the solar radius. Moreover, this is in excellent agreement with the estimate found by Bovy (2020),  $v_c(R_\odot) = 244 \pm 8 \text{ km s}^{-1}$  for  $R_\odot = 8.275 \text{ kpc}$ , or  $v_c(R_\odot) = 242 \pm 8 \text{ km s}^{-1}$  for our adopted value of  $R_\odot$ . Our solution has an average slope  $s = -4.18 \pm 0.02 \text{ km s}^{-1} \text{ kpc}^{-1}$ , fitted for  $14.5 \text{ kpc} < r < 26.5 \text{ kpc}$ , which is comparable to the corresponding value of  $s = -3.93 \pm 0.15 \text{ km s}^{-1} \text{ kpc}^{-1}$  measured from the rotation curve of Jiao et al. (2023), and in much better agreement than the corresponding slope of the NFW-MW model (see also Fig. 5 for comparison).

Using the GD-1 observables, we have computed the present Galactocentric distance projected onto the plane  $z = 0$ , finding that it lies inside the interval  $11.5 \text{ kpc} \lesssim r \lesssim 16.4 \text{ kpc}$  displayed as a vertical shaded (grey) band in the Galaxy RC of Fig. 5. The GD-1 stream orbit location corresponds to  $z \in [2.6, 9.7] \text{ kpc}$  and thus explores the non-sphericity of the full MW models (due to baryons/NFW axisymmetry). It is noticeable that both models approximately agree in their circular velocity values in the GD-1 region. The present Galactocentric distance (not projected) corresponds to the interval  $14.3 \text{ kpc} \lesssim r \lesssim 15.4 \text{ kpc}$ . The stream orbit in the Fermionic-MW has a pericentre of  $14.3 \text{ kpc}$  and an apocentre of  $24.5 \text{ kpc}$ , implying that the stream is currently at its pericentric passage.

It is interesting to display the values of the acceleration vector as a function of the position along the stream. In Fig. 6 we have computed the cylindrical components of the acceleration,  $a_r$  and  $a_z$ , for both MW models, along the stream as a function of  $\phi_1$  (top),  $r$  (middle) and  $z$  (bottom). This plot proves that both models agree in the values of their accelerations along the stream, thus supporting the idea that cold tidal streams are excellent accelerometers (Ibata et al. 2016; Nibauer et al. 2022; Craig et al. 2023).

**Fig. 6.** Cylindrical Galactocentric components of the acceleration along the GD-1 stream, as a function of  $\phi_1$  (top),  $r$  (middle) and  $z$  (bottom), for both the NFW-MW and the Fermionic-MW models. Cold stellar streams are excellent accelerometers.

With respect to virial quantities, the *core-halo* dark matter solution has a finite virial radius  $r_{\text{DM, vir}} = 27.4$  kpc and a virial mass  $M_{\text{DM, vir}} = 1.4 \times 10^{11} M_\odot$ . The total baryon mass of our model is  $M_b = 0.9 \times 10^{11} M_\odot$ , so the total virial mass amounts to  $M_{\text{vir}} = 2.3 \times 10^{11} M_\odot$ . The value of the MW total mass at 50 kpc reported in Table 3 of Gibbons et al. (2014) is  $2.9 \times 10^{11} M_\odot$  with  $(\sigma, 2\sigma) = (0.4, 0.9) \times 10^{11} M_\odot$ , so our solution lies in the  $2\sigma$  region. It should be noted that the mass of the fermionic solution is constant for radii larger than  $r_{\text{DM, vir}}$ , while the mass of the model studied by Gibbons et al. (2014) continues to increase with radius according to their Table 3, though their estimations at large radii have relatively high error bounds, e.g.  $2\sigma = 3 \times 10^{11} M_\odot$  for  $M(200 \text{ kpc}) = 5.6 \times 10^{11} M_\odot$ .

Most recent MW's mass estimations are those obtained by Jiao et al. (2023) and Ou et al. (2023) from Gaia DR3 data, which report data compatible with even smaller values of the MW virial mass:  $1.99^{+0.09}_{-0.06} \times 10^{11} M_\odot$  and  $2.13^{+0.17}_{-0.12} \times 10^{11} M_\odot$  respectively,

in agreement with our fermionic model predictions. These MW mass estimates correspond with a sharp Keplerian decline of the MW rotation ending at  $\approx 26.5$  kpc (with an enclosed dynamical mass at such radius of  $\approx 2 \times 10^{11} M_\odot$ , Jiao et al. 2023), again in remarkable agreement with the virial radius predicted by our Fermionic-MW model of  $\approx 27$  kpc.

The fitted fermionic DM model has a density at the solar neighbourhood of  $\rho_{\text{DM}, \odot} = 1.46 \times 10^7 M_\odot \text{ kpc}^{-3} = 0.55 \text{ GeV cm}^{-3} c^{-2}$  which falls within the  $2\sigma$  region of the estimation made by Salucci, P. et al. (2010).

### 3.3. An example of the S-cluster fit: the paradigmatic case of the S2 orbit

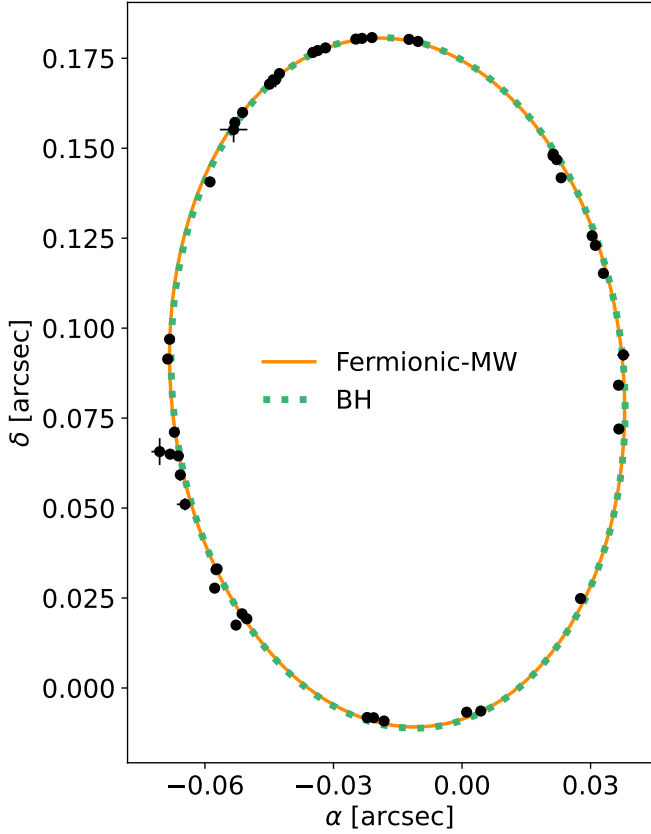

In this section we answer the relevant question of how well the fermionic model that fits the stream according to the procedure of Section 3.1, can fit the iconic S2 star orbit with focus in Sagittarius A\*. Even if a good fit is expected since the core mass of the DM distribution  $M_{\text{core}} = 3.5 \times 10^6 M_\odot$  was carefully fitted together with the stream constraint, it is important to notice that the free parameters of the Fermionic-MW model are not precisely the same as the ones obtained in Becerra-Vergara et al. (2020). That is, while in Becerra-Vergara et al. (2020) the free DM model parameters were obtained to explain the S2 star geodesic together with the MW RC as given in Sofue (2013), here the DM halo region was instead fitted in order to reproduce the GD-1 stream, with somewhat different  $(\beta_0, \theta_0, W_0)$  values.

We have thus performed a least squares fitting procedure following Becerra-Vergara et al. (2020), for the case of the S2 orbit as an example. As commented above, in this case we use the Fermionic-MW DM model which best fits the GD-1 stream, that is  $(\theta_0, \omega_0, \beta_0) = (36.033, 27.3225, 1.2539 \times 10^{-5})$ , obtaining excellent results. In Fig. 7 we show the projected S2 orbit in the plane of the sky while in Fig. 8 we show the time evolution of the redshift function  $z$  (which is directly related to the heliocentric radial velocity according to Equation (C.17a) in Becerra-Vergara et al. 2020),  $\alpha$  and  $\delta$ , for the best fitting values of the *osculating* orbital parameters. These values are given in Table 1, along with the model predicted value of periapsis precession per orbital period,  $\Delta\phi$ , and the orbital period,  $P$ .

Our fitting procedure is applied in the gravitational field of two different scenarios: a Fermionic-MW DM model for  $m = 56 \text{ keV } c^{-2}$  and  $M_{\text{core}} = 3.5 \times 10^6 M_\odot$ ; and a Schwarzschild BH model with central mass of  $M_{\text{BH}} = 4.075 \times 10^6 M_\odot$ . The resulting values for the  $\chi^2_{\text{S2}}$  minimization presented in Table 1, are in perfect agreement with the ones obtained in Becerra-Vergara et al. (2020). We have used the latest public accessible data from Do et al. (2019).

For the exemplified case of the S2 star, a distinction between the models is manifested in the predicted value of the relativistic precession of the S2 periapsis  $\Delta\phi$ . This interesting relativistic effect in the case of a regular (i.e. non singular) DM core was confronted with the publicly available astrometric data of S2 and carefully compared with the BH case in Argüelles et al. (2022). There it was shown that larger particle masses (i.e. leading to more compact DM cores as detailed in section below), implies less amount of extended DM mass filling the S2 orbit. Thus, precession grows from retrograde to prograde as it tends to the unique value predicted by the BH model. Indeed in Argüelles et al. (2022) it was shown that already for particle masses of  $m = 60 \text{ keV } c^{-2}$  slightly above the value here considered of  $m = 56 \text{ keV } c^{-2}$ , the periapsis precession is very close the one predicted by the Schwarzschild BH. On the contrary, for particle

**Fig. 7.** Modelled and observed projected orbit in the sky for a Fermionic-MW DM model in a solid (amber) line and a BH of  $M_{\text{bh}} = 4.075 \times 10^6 M_{\odot}$  in a dotted (green) line.

**Table 1.** Best-fitting *osculating* orbital parameters of the orbit of the S2 star for two different models. A fermionic DM model with  $m = 56 \text{ keV } c^{-2}$ , core mass  $M_{\text{core}} = 3.5 \times 10^6 M_{\odot}$ , and a BH of mass  $M_{\text{bh}} = 4.075 \times 10^6 M_{\odot}$ .

Parameter	Fermionic-MW	BH
$a$ [as]	0.1250	0.1253
$e$	0.8868	0.8861
$\omega$ [°]	66.93	66.50
$i$ [°]	134.40	134.44
$\Omega$ [°]	228.20	228.05
$P$ [yr]	16.051	16.049
$\Delta\phi$ [arcmin rev $^{-1}$ ]	-6.04	11.95
$\chi^2_{\text{S2}}$	3.1845	3.3826

masses  $m \lesssim 56 \text{ keV } c^{-2}$  the DM core is too extended in radius producing large values of retrograde S2 periastron precession and poorer orbit fits [Becerra-Vergara et al. \(2020\)](#); [Argüelles et al. \(2022\)](#).

### 3.4. Varying the fermion mass to reach more compact cores

As already mentioned, we have found a fermionic solution that is in agreement with both GD-1 data and the geodesic motion of the best studied S-cluster star around Sagittarius A\*, the S2 star. But it is also true that this S-stars constraint will be also satisfied by any fermionic DM profile with a core mass  $m_c \approx M_{\text{core}}$  and

**Fig. 8.** Redshift ( $z$ ), right ascension ( $\alpha$ ) and declination ( $\delta$ ) as a function of time epoch for the same models displayed in Fig. 7.

more compact cores than the solution corresponding for  $m = 56 \text{ keV}$ . It is therefore interesting to find out how much compactness can be reached while keeping both the S2 star and GD-1 constraints, in the light of the new observations of the Event Horizon Telescope ([Collaboration 2022](#)), where a shadow angular diameter of  $48.7 \pm 7.0 \mu\text{as}$  has been measured. This diameter corresponds to a shadow radius of  $\sim 2.46$  Schwarzschild radii assuming a black hole mass of  $M_{\text{bh}} = 4.075 \times 10^6 M_{\odot}$ . In order to extend the fermionic solutions to other values of the fermion mass ( $m$ ), we used the second optimization algorithm described in Sec. 2.4 for  $m = 100, 200, 300$  and  $360 \text{ keV } c^{-2}$ . For each fermion mass we divided a given macroscopic orthohedron<sup>5</sup> in parameter space in  $20^3 = 8000$  smaller orthohedrons. In each subregion we performed an independent optimization in a parallel distributed scheme, searching for those parameters that minimize  $\chi^2_{\text{full}}$  with the NOMAD algorithm. Afterwards, we selected the global minimum by comparing the results of each distributed process. The result is that for all the fermion masses it is possible to find values of the other parameters in such a way that both the GD-1 stream and the core mass constraints are respected with the same precision as in the initial ( $m = 56 \text{ keV } c^{-2}$ ) case. In fact, as shown in Fig. 9, all the solutions have the same density profile in the halo region, while their difference is limited to the compactness of the core. The values of the core radii of these

<sup>5</sup> The lower and upper bounds of the orthohedrons were given by lower =  $(36, 27, 1.2 \times 10^{-5})$ ,  $(37, 28, 5 \times 10^{-5})$ ,  $(38, 29, 3.5 \times 10^{-4})$ ,  $(40, 29, 1.3 \times 10^{-3})$  and upper =  $(40, 31, 10^{-4})$ ,  $(41, 32, 10^{-3})$ ,  $(42, 32, 3 \times 10^{-3})$ ,  $(44, 32, 4 \times 10^{-3})$ , respectively for  $m = 100, 200, 300, 360 \text{ keV } c^{-2}$  in  $(\theta_0, \omega_0, \beta_0)$  space.

**Fig. 9.** Fermionic DM density profiles with different core-compacities (i.e. different  $m$ ) fitting both, the GD-1 stream and the DM core mass which agree with the S2 star data orbiting Sagittarius A\*. The Schwarzschild radius is computed assuming a black hole mass  $M_{\text{bh}} = 4.075 \times 10^6 M_{\odot}$ .

solutions are approximately 1096, 232, 35, 10, 5 Schwarzschild radii for  $m = 100, 200, 300, 360$  keV  $c^{-2}$ , respectively. The last analysed value of  $m = 360$  keV  $c^{-2}$  corresponds with a DM core which is very close to the last stable solution according to stability criterium of Argüelles et al. (2021), leading to the gravitational core-collapse into a BH of about  $4 \times 10^6 M_{\odot}$ .

## 4. Conclusions

We have fitted both, the GD-1 stream located at about 14–15 kpc from the Galaxy center together with the S2 star orbit located at milli-pc scales, in a MW potential consisting of a fermionic *core-halo* DM distribution (Argüelles et al. 2018; Becerra-Vergara et al. 2020, 2021; Argüelles et al. 2022), plus a fixed baryonic distribution (Pouliasis et al. 2017). Remarkably, the resulting MW total mass and virial radius of the Galaxy predicted by the fermionic DM model is in excellent agreement with both, the virial mass of  $\approx 2 \times 10^{11} M_{\odot}$  and the Galactocentric radial range of  $\approx 20 - 26$  kpc in which the MW rotation curve sharply drops as recently measured by Gaia DR3.

We obtained the free parameters of the fermionic model by fixing the fermion mass and fitting simultaneously two astrophysical constraints: the stream observables and a DM core mass of  $3.5 \times 10^6 M_{\odot}$ , the latter taken from previous fits of the S-stars cluster at the centre of the Galaxy with no central BH (Becerra-Vergara et al. 2020, 2021). We could thus reproduce with high accuracy, and for fermion masses ranging from 56 to 360 keV  $c^{-2}$ , the polynomials fitted by Ibata et al. (2020) that correspond to observed sky position, proper motion, photometric distance and radial velocity of the stream.

In order to compare with other GD-1 fits in the literature, we have also fitted the stream progenitor initial conditions with the axisymmetric generalization of the NFW distribution from Malhan & Ibata (2019), obtaining agreement in the GD-1 phase-space track of both the Fermionic-MW and the NFW-MW models. Additionally, we have obtained agreement between both models in the rotation curves at projected ( $z = 0$ ) Galactocentric distances,  $r$ , corresponding to the stream observables, i.e.  $11.5 \leq r \leq 16.4$  kpc. The average slope of the rotation curve between 14.5 and 26.5 kpc obtained from the Fermionic-MW model was  $s = -4.18 \pm 0.02$  km  $s^{-1}$  kpc $^{-1}$ , in much better agree-

ment with the recent observations of Jiao et al. (2023) than the NFW-MW model. Regarding the acceleration field, we have shown that both MW models perfectly agree in their acceleration vectors as a function as the position along the stream.

We have found a circular velocity at the Sun's position of  $v_c(R_{\odot}) = 244$  km  $s^{-1}$ , in line with the value independently obtained by Malhan & Ibata (2019).

The fermionic DM solution has a finite radius of  $r_{\text{DM,vir}} = 27.4$  kpc and a virial mass of  $M_{\text{DM,vir}} = 1.4 \times 10^{11} M_{\odot}$ , implying a total (DM plus baryons) virial mass of the galaxy of  $M_{\text{vir}} = 2.4 \times 10^{11} M_{\odot}$ , which is at  $2\sigma$  from the value reported in Table 3 of Gibbons et al. (2014) for a radius of 50 kpc. The value obtained for the DM density at the solar neighbourhood is  $\rho_{\text{DM},\odot} = 1.46 \times 10^7 M_{\odot} \text{ kpc}^{-3} = 0.55 \text{ GeV cm}^{-3} c^{-2}$ , which falls inside the  $2\sigma$  region of a previous estimate by Salucci, P. et al. (2010).

Finally, we have shown that it is possible to find a one-dimensional family of solutions parameterized by the fermion mass, having the same halo that fits the GD-1 stream but differing in the compactness of the central core, and always reproducing the S2 star orbit (see Figs. 7 and 8 for the case of  $m = 56$  keV). For the limiting case studied here ( $m = 360$  keV) we obtained a core radius of  $r_c \approx 5$  Schwarzschild radii. A precise relativistic ray tracing study about simulated ring-like images of the central cores of fermionic distributions is on progress, trying to put strict constraints on the minimum compactness needed to be in agreement with the EHT observations.

In summary, the findings of this work not only support the idea that cold tidal streams are excellent probes of the acceleration field of the Milky Way, but show that the (spherical) fermionic model is capable to fit independent set of observables covering three totally different Galaxy distance scales:  $\sim 10^{-6}$  kpc (S-cluster),  $\sim 14$  kpc (GD-1) and  $\sim 30$  kpc (GAIA DR3 RC mass estimates).

**Acknowledgements.** MFM would like to dedicate this work to the memory of a great friend since childhood, Gustavo Fabián Larrion (1980-2021), Q.E.P.D. MFM thanks Khyati Malhan for his comments about the NFW-MW model. MFM thanks Leandro Martínez, Ian Weaver, Joaquín Pelle and the JULIA community for their great support with the language and workflow. We thank Jorge A. Rueda for his comments about the manuscript. We thank Juan Ignacio Rodríguez for his great support with hardware and software issues regarding the IALP server and personal computers. We thank Federico Bareilles and the informatic support team of the FCAGLP for their help during these years. This work used computational resources from CCAD – Universidad Nacional de Córdoba (<https://ccad.unc.edu.ar/>), which are part of SNCAD – MinCyT, República Argentina. This work also used computational resources from the HPC center DIRAC, funded by Instituto de Física de Buenos Aires (UBA-CONICET) and part of SNCAD-MinCyT initiative, Argentina. DDC and MFM acknowledge support from CONICET (PIP2169) and from the Universidad Nacional de La Plata (G168). C.R.A. acknowledges support from CONICET, the AN-PCyT (grant PICT-2018-03743), and ICRA.Net. VC thanks financial support from CONICET, Argentina. The figures presented in this work were made with the *AlgebraOfGraphics.jl* (<https://aog.makie.org/dev/>), *Makie.jl* (Danisch & Krumbiegel 2021) and *Matplotlib* (Hunter 2007) packages. Some of our optimization results were initially guided by the use of the LN\_NELDERMEAD (Nelder & Mead 1965; Box 1965; Shere 1974) algorithm, from the *NLOpt.jl* (Johnson 2007) package. In order to run JULIA in a parallel SLURM environment we made use of the *Distributed.jl* and *SlurmClusterManager.jl* packages.
